Abstract
We describe a general approach decomposing a function into a sum of functions, each with a smaller input size than the original. Hence we can map such functions with essentially the same precision using small ROM tables and adders. We derive an easy method to compute the worst case error for many elementary functions and an error bound for the rest. Important applications are reciprocals, logarithms, exponentials and others.

Index Terms – reciprocal, logarithm, exponential, table look-up, function decomposition

1 Introduction
There are increasing needs in evaluating elementary functions such as reciprocals, square roots, logarithms, exponentials and trigonometric functions quickly. In evaluating a function \( f(X) \), if \( X \) has a small number of values, we can preprocess the values of \( f(X) \) for all \( X \) and store them in a table. Such an approach is limited by the table size available.

However, for elementary functions, we have found that instead of one large table we can use several smaller tables and add their outputs. The input \( X \) is split into two or more overlapping subsets \( X_k \)'s. Each \( X_k \) has fewer bits than the original \( X \). The \( X_k \)'s are the inputs for the smaller tables. The outputs of the tables are added together yielding \( f(X) \). In fact this only yields an approximation of \( f(X) \), but the error matches the precision bound. The proposed method is efficient for DSP operations in which rather short word length (e.g. 16-24 bits) is requested and in initial approximations for converging methods such as Newton-Raphson to compute elementary functions with larger bits.

To explain this task by a practical example, think of a logarithm table book. Assume it allows the user to look up the logarithm of some number \( z \), where \( z \) has 6 decimal digits. Hence it must contain 1,000,000 entries, a pretty substantial table. Following our approach, we can take the first four digits of \( z \), look it up in a small table; then take the first two and the last two digits and look it up in another small table. The sum of the two table entries provides the logarithm. The table size is greatly reduced. Instead of one large table we have only two small tables with 20,000 entries all together, an improvement by a factor of 50. To illustrate the task by a numerical example consider the computation of \( \log_{10} 654321 \approx -.184209 \). Our approach suggests to compute \( \log_{10} 6543 + \log_{10} 650021 - \log_{10} 65 \approx -.184209 \) instead. We can look up the first logarithm in the first table (only the first four digits are needed) and the sum of the other two logarithms in the second table (only the first two and last two digits are needed).

Table look up algorithms are used, for instance, to compute initial solutions for reciprocal and division. DasSarma and Matula [3] give a good overview. Range reduction has already been discussed in other papers [4], though with rather different approaches. We are not aware of any algorithm similar to our approach. The theory behind our method uses so called Partial Product Arrays (PPA). This method was introduced by Stefanelli [7] in the early '70's. Stefanelli developed PPA's to perform binary division. Later, others have used PPA's to compute functions like square root, logarithm, exponential and trigonometric functions [1, 2, 5, 6].

A PPA is a symbolic representation of a function by the input bits. If we create the PPA of some function \( f(X) \) we get a large number of bit products. Added together at their proper places of significance they generate \( f(X) \). It is possible to create the PPA for any of the discussed functions up to some degree of accuracy.

The main question on the proposed method is the error caused by splitting the input bits into several smaller inputs. The model allows us to derive upper bounds on this error for arbitrary splittings. For certain functions, like reciprocal, logarithm and exponential we even gain sharp error bounds and can determine the worst case error exactly.

In Section 2 we define PPA's and make some observations. This allows us, in Section 3, to derive an approximation formula and to compute the worst case error. Section 4 gives an outline of some applications of the method presented. Limitations and open questions are discussed in Section 5.

2 Partial Product Arrays
We evaluate functions that can be developed into converging series \( f(X) = \sum_{k=0}^{\infty} a_k X^k \) up to some precision. For our aim, the number of bits of the parameter
X is crucial, because more input bits require larger tables. The facts that the a_i's have limited precision as well and that we talk about infinite series are not so important now. Of course, we approximate infinite series by finite ones. Let us consider parameter X and its powers more closely. 

X is a nonnegative fixed point number and consists of a string of bits, \( X = b_1 \cdots b_n \). (For certain cases we will assume that the radix point is such that \( X = .b_1 \cdots b_n \) The series can be written as:

\[
\sum_{i=0}^{\infty} a_i[b_1 \cdots b_n]^i
\]

In the subsequent discussion we assume that the a_i's are all nonnegative. We call such functions a_nonnegative functions. General functions which have both negative and positive coefficients, can be separated into positive and negative parts: \( f(X) = f_p(X) - f_n(X) \). Each \( f_i \) is an a_i-nonnegative function. Note that the functions \( 1/(1-X), -\log(1-X) \) and \( 2^X \) are a_i-nonnegative. (We later define the first two functions only for \( 0 \leq X < 1/2 \).) We compute the function \( f(X) \) in a bitwise and symbolic way. All powers of X are expressed in bit notation.

**Example 1**

Consider a symbolic two-bit number \( X = [b_1 b_2] \equiv b_1 2^{-1} + b_2 2^{-2} \). Squaring X yields \( X^2 = b_1 2^{-2} + b_1 b_2 2^{-2} + b_2 2^{-4} \). (Note that we write \( b_1 \) instead of \( b_1^2 \) because we are dealing with single bits.) The cube of X is then, after simplification, \( X^3 = b_1 b_2 2^{-2} + b_1 b_2 2^{-3} + b_1 b_2 2^{-5} + b_2 2^{-6} \). Multiplying by some constant \( a_i \) spreads these bit products further to different places of significance; for instance \( [.1011] \times b_1 b_2 2^{-2} \) becomes \( b_1 b_2 2^{-3} + b_1 b_2 2^{-5} \). Consider a simple example for a symbolic representation of a function. Take \( f(X) = X + X^2 + X^3 \). \( f(X) \) is then \( b_1 b_2 2^{-1} + b_1 b_2 2^{-2} + b_1 b_2 2^{-3} + b_1 b_2 2^{-4} + b_1 b_2 2^{-5} + b_2 2^{-6} \). We get symbol bit products weighted by some power of two. This simple example serves as an illustration for a definition of a positive PPA.

**Definition 1**

A positive PPA of an a_i-nonnegative function \( f[b_1 \cdots b_n] \) is the representation of the function as a sum of nonnegative bit products, i.e.

\[
f[b_1 \cdots b_n] = \sum_{j=1}^{S} B_j 2^j
\]

where each nonnegative bit product \( B_j \) is \( b_{j_1} \times \cdots \times b_{j_k} \) and the bits of each product are a subset of the input bits; \( \{b_{j_1}, \cdots, b_{j_k}\} \subseteq \{b_1, \cdots, b_n\} \).

Each a_i-nonnegative function can be developed into a positive PPA. Our definition of PPA's is a very basic one. Compare, for instance, with Schwarz [6]. He uses more general bit products, allowing signed products and logic complements of single bits. His goal is to derive a hardware design from a PPA. Our simplification rules are very simple, there is only one:

\[
B2^2 + B2^2 \rightarrow B2^{2+1}
\]

Generally the symbolic representation of \( f(X) \) contains all possible bit products out of \( X \), all of which are nonnegative. The PPA of \( f([1 \cdots 1]) \) (all bits 1) contains, for all possible bit products, a weighted 1 accordingly (i.e. none of them is made zero). We observe

\[
0 \leq f(X) \leq f([1 \cdots 1])
\]

Let us consider for instance the development of the reciprocal function into its PPA. We compute

\[
\frac{1}{1-X} = \sum_{i=0}^{\infty} X^i
\]

to compute all bit products. For this case it makes sense to assume \( 0 \leq X < 1/2 \), where \( X = [.0b_2 \cdots b_n] \equiv b_2 2^{-2} + b_2 2^{-3} + \cdots + b_n 2^{-n} \) and we can proceed as in Example 1. We can calculate a finite sum \( \sum_{i=0}^{L} X^i \) such that the error matches the precision bound \( 2^{-n} \). We get

\[
1/(1-X) = 1+b_2 2^{-2}+b_3 2^{-3}+\cdots,
\]

see equation (3).

The simplification rule (2) implies that, finally, there are no two equal bit products with equal weight. Hence the simplified PPA of \( f(X) \) can be interpreted as a set. We denote it by \( P(f(X)) \). (Note that we use \( X \) both to refer to the input of function \( f \) and to the set of symbolic input bits, \( \{b_1, \cdots, b_n\} \).) \( P(f(X)) \) is then a set of bit products times the appropriate power of two, and can be regarded as a subset of \( 2^X \times \{1, \cdots, n\} \) (Note that such a set definition covers functions up to a precision of \( n \) bits. In theory, of course, \( n = \infty \)). For instance, in Example 1 we can derive the set \( P(f(X)) = \{(b_1, b_2, 1), (b_1, 1, 1), (b_1, 2, 1)\} \) from \( f(X) \).

Assume certain input bits are constantly zero. All symbolic bit products of the PPA which contain these zero-bits will disappear, too. The set of variable bits becomes smaller, only a subset \( X_1 \) of \( X \), the original symbolic input bits is used. It is then obvious that also \( P(f(X)) \subseteq P(f(X)) \), i.e. \( f(X_1) \) generates only a subset of all bit products of \( f(X) \). Look at the PPA in equation (3) above. If we use the input subset \( X_1 = \{b_2, b_4\} \subseteq X = \{b_2, b_3, b_4, \cdots\} \), we calculate \( f(X_1) = 1/(1-.0b_2 b_4 0) \), there remain the products which contain only \( b_2 \) and \( b_4 \).

We call a function \( g(X) \) where \( P(g(X)) \subseteq P(f(X)) \) an approximation of \( f(X) \). If we unite such approximation sets we get a set describing another (possibly better) approximation. In the following proposition we observe that such unions can be found by addition and subtraction of the function, using various input subsets.

**Proposition 1** Given a function \( f(X) \) representable as a PPA, \( P(f(X)) \), and an approximation \( g(X) \) such that \( P(g(X)) \subseteq P(f(X)) \) and the input subset \( X_1 \)
on the common input bits \(\{b_1, \ldots, b_n\}\). The union of the two approximations is a function \(h(X)\) i.e. 
\[ P(h(X)) := P(g(X)) \cup P(f(X)) \]. We make the following observation:
\[ h(X) = g(X) + f(X_1) - g(X_1) \]
and \(P(h(X)) \subseteq P(f(X))\).

Example 2

Consider for instance \(f_{ab}(X)\) of Example 1. Given is the approximation \(g(X) = b_1b_22^{-1} + b_12^{-1} + b_22^{-2}\); note that \(P(g(X)) \subseteq P(f_{ab}(X))\). We get another approximation by using the input subset \(X_1 = \{b_1\}\) on \(f_{e}(X)\). All products which contain \(b_2\) disappear and \(f_{e}(X_1) = b_12^{-1} + b_12^{-2} + b_12^{-3}\). We add \(f_{e}(X_1)\) to \(g(X)\) and subtract the products which appear twice, i.e. \(g(X_1) = b_12^{-1}\). Then \(h(X) = b_1b_22^{-1} + b_12^{-1} + b_12^{-2} + b_12^{-2} + b_12^{-3}\) and \(P(h(X)) \subseteq P(f_{e}(X))\).

With Proposition 1 we can define recursively the union of several sets \(P(f(X))\) by function addition and subtraction. Assume that the union of \(m - 1\) subsets is given by \(g(X) = \bigcup_{r=1}^{m-1} P(f(X_r)) = P(f(X_m))\), where each \(a_r = \pm 1\) and \(G_r\) are appropriate input subsets. Then with Proposition 1 we get:

\[
\bigcup_{r=1}^{m} P(f(X_r)) := g(X) + f(X_m) - g(X_m) \tag{4}
\]

3 Subset approximations

3.1 General Approximation

The set considerations of the previous sections allow us to derive an approximation formula and to estimate its error. Formula (4) above provides an iterative generation of approximations for \(f(X)\). The basic idea is that we unite smaller sets to approximate the \(P(f(X))\). It is not possible to generate all products in this way. However, we get all significant ones, i.e. those within the precision limit.

Definition 2 Assume input subsets \(X_1, X_2 \cdots \subseteq X\). 

\[ g_1(f(X), X_1) := f(X) \text{ and iteratively} \]

\[ g_k+1(f(X), X_1, \ldots, X_{k+1}) \] = \[ g_k(f(X), X_1, \ldots, X_k) + f(X_{k+1}) - g_k(f(X), X_1 \cap X_{k+1}, \ldots, X_k \cap X_{k+1}) \]

For easier notation we define

Definition 3 \(A_k(f(X)) := g_k(f(X), X_1, \ldots, X_k)\).

Two examples are \(A_2(f(X)) = f(X_1) + f(X_2) - f(X_1 \cap X_2)\) and \(A_3(f(X)) = f(X_3) + f(X_2) - f(X_1 \cap X_2) + f(X_3) - f(X_1 \cap X_3) - f(X_2 \cap X_3) + f(X_1 \cap X_2 \cap X_3)\) and one addition. More generally, in the first table \(T_1(X_1) := A_1(f(X))\) and in the \(k\)-th table \(T_k(X_k) := A_k(f(X)) - A_{k-1}(f(X))\). To evaluate all functions for the \(k\)-th table we need only the input set \(X_k\) and subsets of it, respectively. These considerations boil down to the fact that the mapping of \(A_k\) needs \(k\) tables and \(k-1\) additions. There is, of course, a rounding error, too, due to the limited table output. However, if the output chosen is long enough, this error is small, compared to the approximation error. Each approximation \(A_k(f(X))\) corresponds to a subset of \(P(f(X))\).

Next we consider the approximation error. Up to now we do not even know which subsets are good or bad. Good approximations will cover all higher significant bit products of \(f(X)\). The quality of an approximation can be derived by a simple observation. \(P(f(X))\) consists only of positive products and \(P(A_k(f(X))) \subseteq P(f(X))\). Hence, we get following proposition:

Proposition 2 For an approximation \(A_k\) there is

\[ \max (f(X) - A_k(f(X))) = f([1 \cdots 1]) - A_k(f([1 \cdots 1])) \]

Proposition 2 derives a sharp bound on the approximation error. Note that it is restricted to \(a_i\)-nonnegative functions. General functions are considered as the difference between two \(a_i\)-nonnegative functions, \(f(X) = f_1(X) - f_2(X)\). There is a positive error both from \(f_1\) and \(f_2\). The worst case happens when one is large and the other zero, which concludes following proposition:

Proposition 3 For a function \(f(X) = f_1(X) - f_2(X)\), each \(f_i\) \(a_i\)-nonnegative, there is

\[ |f(X) - A_k(f(X))| \leq \max (f_1([1 \cdots 1]) - A_k(f_1([1 \cdots 1])), f_2([1 \cdots 1]) - A_k(f_2([1 \cdots 1]))) \]

Example 3

To see how Proposition 2 works, consider the following 2-table example. Assume we want to approximate the function \(f(X) = \ln(1 - X) = \sum_{i=1}^{\infty} X^i / i\) with \(0 < X < 1/2\). Parameter \(X\) consists of 22 bits (\(X = [0.0b_2 \cdots b_{24}]\)). We want to use two ROM tables each with only 16-bit input.

From Definition 2 we derive the approximation \(A_2(\ln(1 - X)) = \ln(1 - X) - \ln(1 - X_2) + \ln(1 - X_1 X_2)\). We decide to choose the input subsets \(X_1 = [0.0b_2 \cdots b_{100} \cdots 0b_{16} \cdots b_{24}]\) and \(X_2 = [0.0b_2 \cdots b_0 \cdots 0b_{16} \cdots b_{24}]\). Each \(X_k\) contains 16 variable bits. Proposition 2 allows us to compute the worst case error as follows:

\[ -\ln(1 - (5.2^{-24})) + \ln(1 - (5.2^{-17})) + \ln(1 - (5.2^{-10}) + 2^{-17} - 2^{-24})) - \ln(1 - (5.2^{-10})) < 98 \times 2^{-25} \]

(We calculate the logarithm with a better precision than \(2^{-25}\). Hence, we can add the output of the table \(T_1(X_1) = \ln(1 - X_1)\) to that of \(T_2(X_2) = \ln(1 - X_2) + \ln(1 - (X_1 X_2))\) and round it to 24 bits to the right of the radix point. Remember that there is a positive error, i.e. \(f(X) - A_2(f(X)) > 0\). We exploit this fact, too, and map to the first table \(T_1(X_1) = \ln(1 - X_1) + .98 \times 2^{-26}\). Instead, we can further reduce the final error of the rounded value by a factor of 1/2. Note that we omit in this discussion the so-called Table maker dilemma, which is the impossibility of doing exact rounding on prerrounded values [4].

Two other problems are demonstrated by the above example. The first is, how did we decide which subsets
Table 1: The table shows number and size of ROM's to map \( \ln(1 - X) \) with an error less than \( 2^{-25} \). In the cases of 3 and 5 ROM tables one of the tables is smaller in size. To compute \( \ln(Y) \) we assume \( Y = [1.w_2 \ldots w_{24}] \). The transformed parameter is then \( X = [0.b_0 \ldots b_{24}] \). The number of output bits I should be slightly larger than 24. The 20-table case is near the limit of testing and input size. (It would require 19 additions, too.) The according subsets can be found in Appendix 2.

<table>

Table 2: Shown are the ROM-sizes for several elementary functions mapped by two tables. For all cases we assume parameters to the 24th bit right of the radix and map the functions with an approximation error less than \( 2^{-25} \). I should be chosen slightly larger than 24 to keep the rounding error within this range. The according subsets have been generated by the heuristic given in Appendix 2.

(a) For \( 0 \leq X < 1/2 \) and \( 0 \leq a_i \leq 1 \) the error is \( \epsilon < 2^3yz \).

(b) For \( 0 \leq X, 1/4 \geq y \) and \( 0 \leq a_i \leq 1/4 \) the error is \( \epsilon < e^x(yz + 4y^2) \).

The proof can be found in Appendix 1. Theorem 4 provides a good rule of thumb for the 3-block method. It guarantees for many functions that the bit range with \( n \) bits can be divided into three (almost equal) ranges. Hence, the storage is reduced from \( 2^n \) to about \( 2^{n/3} \). However, once the function and the subsets are known, Proposition 2 and 3 provide more accurate bounds.

4 Applications

4.1 Reciprocal

One of the most obvious applications is reciprocation. Fast reciprocation can be used to do fast division. Many algorithms have been proposed to compute reciprocals [3].

Given a number \( Y = [1.w_2 \ldots w_n] \), our task is to compute \( 1/Y \). We transform \( Y \) to \( X = 1 - Y \) and \( X = [0.0w_2 \ldots w_n] < 1/2 \). We can compute \( 1/Y = 1/(1 - X) \) with the approach described in Section 3, using \( 1/(1 - X) = \sum_{i=1}^{\infty} X^i \). A 2-Table approach as discussed in Section 3.2 is possible with an error smaller than the bound given in Theorem 4 (a). See also Table 2 for the 24 bit case. The heuristic of Figure 1 can be used to generate subsets for a larger number of tables as well.

4.2 Logarithm

We already presented subset combinations to compute the natural logarithm of some number \( Y' \). For base 2 logarithms we just multiply by \( \ln 2 \) (also increasing the error by this factor).

We can always scale \( Y' \) by shifting to \( Y = [1.w_2 \ldots w_n] \). To compute \( \ln Y \) we transform \( X = 1 - Y = [0.0w_2 \ldots w_n] \). Then \( 1/(1 - X) = -1/\ln 2 \sum_{i=1}^{\infty} X^i / i \). The outputs of the according tables add up to the logarithm. Finally we get \( \ln(Y') = \ln(1 - X) + \) number of shifts.

Since the function is \( a_i \)-nonpositive we always get a negative error. We assume an approach which gener-
ates the worst case error $\epsilon_w$ less than $2^{-n}$. Subtracting $\epsilon_w/2$ allows virtually exact rounding.

### 4.3 Exponentiation

Consider an approach to compute $2^B = \sum_{i=0}^{\infty} (B \ln 2)^i / i!$. If $B$ has an integer part, it has to be removed and added later to the exponent or used to make appropriate shifts. Assume $B$ is $B = [I, b_1 \cdots b_n]$. The integer part $I$ is removed. To compute $2^{[b_1 \cdots b_n]}$ one can find according subsets with the algorithm of Figure 1, and generate the appropriate ROM tables.

### 5 Limitations and Open Questions

The proposed method exploits properties of fundamental functions, which may not be found in general functions. Especially important is the convergence rate. A function which converges quickly has in the significant bit range relatively small bit products, which are easier to contain in small tables.

The problem of deciding if given input subsets are optimal under certain restrictions is not trivial and quite important, too. Rote of TU Graz has pointed out a connection with Monge matrices to check subsets for optimality. This will be a topic of further investigation.

Another question concerns the minimum input size of the tables. For $0 \leq X = [b_1 \cdots b_n] < 1$ there is a trivial lower limit for the number of input bits $r$. If we use only tables with $r$ input bits we cannot contain bit products which consist of more than $r$ bits. Of all these unnappable bit products the most significant is $[b_1 b_2 \cdots b_{r+1}]$. It is created by $X^{r+1}$ and causes an error $E = a_{r+1} 2^{-(r+2)(r+1)/2}$. To make sure that this error is below the significant range it is required that $E < 2^{-n}$ which we transform to $(r + 1)^2 / 2 > n - \ln a_{r+1}$. For instance the function $1/(1 - X)$ would have a lower limit of roughly $\sqrt{2}n$ for the input bits of the according tables. The actual minimum may be harder to find. However, an approach which uses tables with smallest input size possible does not look promising. A large number of tables has to be used causing many additions, which wipe out the speed advantage of look up’s.

### 6 Conclusion

An approximation algorithm has been presented which allows us to decompose a function $f(X)$ into a sum of functions, each with smaller input. The general idea is to compute functions by several parallel look up’s in small ROM-tables and additions. Hence the overall memory space required is much smaller than that of a direct 1-Table approach. The additional costs are one or a few additions. We have shown how to compute bounds for the worst case error for arbitrary and overlapping input subsets $X_k \subset X$. We can derive the error bound for an arbitrary number of tables and for arbitrary functions which can be developed into a converging series. Included is also a fast heuristic algorithm which generates input subsets. Several examples have been presented with a precision of 24 bits. In these examples we gain a memory improvement by a factor of between 64 and 400. For the general n-bit precision and for general functions (which can be developed into series) we also show a general memory improvement from $2^n$ to about $2^{n/3}$ for the 2-Table approach. We consider the presented method useful for fast hardware implementations of functions like reciprocal, logarithm, exponentiation, division, square root, trigonometric functions and others.

### Appendix 1

**Proof of Theorem 4 (a)** Assume first $a_i = 1$. Then we have to consider function $1/(1 - X) = \sum_{i=0}^{\infty} X_i$.

From Definition 2 and Proposition 2 we get:

$$
\epsilon \geq 1/(1 - X) - A_2(1/(1 - X)) = \frac{1}{1 - x - y - \frac{1}{1 - x - y} - \frac{1}{1 - x - z + \frac{1}{1 - x}}}
$$

(5)

We set $x' = 1 - z$ and $y' = x' - y$. Then (5) becomes:

$$
\frac{1}{y' - z} - \frac{1}{y'} - \frac{1}{y' - z} + \frac{1}{z'} = \frac{z[x'(x' - z) - y'(y' - z)]}{z' y'(x' - z)(y' - z)}
$$

Substituting for $x'^2$ and $y'^2$ we get:

$$
\frac{z(2x'y' - y'^2 - yz)}{z' y'(x' - z)(y' - z)} < \frac{2xy}{z' y'(x' - z)(y' - z)} < 2^4xyz
$$

Because of $x < 1/2$ we have $x' > 1/2$. See above that $z, y$ and $z$ represent different bit ranges and $y > z$. Hence also $y' > 1/2$ and also $x' - z > y' - z > 1/2$. So we can further simplify our estimate to the final bound.

Let us consider now the case for more general $a_i$. The error is:

$$
\epsilon = f(X) - A_2(f(X)) = \sum_{i=0}^{\infty} a_i(X^i - (x + y)^i - (x + z)^i + z^i)
$$

Since there is $0 \leq a_i < 1$ and because all sum terms are $a_i$-nonnegative we simplify the estimate to

$$
\epsilon < \sum_{i=0}^{\infty} (X^i - (x + y)^i) - (x + z)^i + z^i = 1/(1 - X) - A_2(1/(1 - X)) < 2^4 yz
$$

**Proof of (b).** The error is $\epsilon = f(x + y + z) - A_2(f(x + y + z))$ and we set $a_i = 1/i!$. Then $\epsilon = e^{x+y+z} - e^{x+y} - e^{x+z} + e^z$. We write it as:

$$
e^{x}(e^y - 1)(e^z - 1)
$$

(6)

The infinite series formula for $e^x = \sum_{i=0}^{\infty} x^i/i!$. We approximate these products by the first two terms and give an upper bound for the rest, yielding

$$
(e^y - 1) < y + y^2/(1 - y)
$$
Similarly for \( z \). Substituting \( e^y - 1 \) and \( e^z - 1 \) by their upper bounds in equation (6), replacing all higher order terms \( z \) by \( y \), reduce \( y^6 \) to \( y^6/4 \) and replace \( (1 - y) \) by \( 3/4 \), respectively, yields the upper bound. Then we get the upper bound

\[
e < e^z(yz + 4y^3)
\]

\( \square \)

## Appendix 2

Figure 1 describes the heuristic we used to find input subsets. In the heuristic we use integers to describe subsets and partial products, \( X_k \) and \( Z \). The union of two such sets is simply bitwise OR. A partial product \( b_k b_{k+1} \) corresponds to \( Z = 1000110 \). In principal all possible partial products could be counted through, but the heuristic is speeded up tremendously by skipping partial products which are beyond significance in step (G3). ROMSIZE is the number of input bits for the ROM. Each subset has maximum ROM-size elements. To test the size of a subset we count the number of 1-bits of the according integer. The variable \( Bound \) is the error bound which must finally be fulfilled by the subsets. To compute \( error(f, subsets) \) the algorithm uses Proposition 2.

The main idea of the heuristic is to generate the most significant products of the PPA of \( \sum_{i=0}^{n} X^i \). The found subsets can also be used for functions with sum coefficients \( 0 \leq a_i < 1 \). The heuristic is easy to program, very fast and needs (for most cases) much less memory than programming the full PPA.

\[
\text{GenerateSet}(f,X,\text{ROMSIZE},N,\text{Bound})
\]

(S0) \( \text{significance}(Z) := \text{sum of all non zero bit positions; (e.g. \text{significance}(1100110) = 6 + 5 + 2 + 1) \}
\]

(G1) \( Precision := \text{Inputbits} (= \text{length of } X) \)

(G2) For \( k = 1 \) To \( N \) \( X_k := \{ \} \)

(G3) For \( Z = 0 \) To \( 2^{\text{Inputbits}} - 1 \)

\{ If \( \text{significance}(Z) \leq \text{Precision} \) \}

Seek first subset \( X_k \) with \( \text{hamming}(Z \cup X_k, 0) \leq \text{ROMSIZE} \)

Else Increment \( Z \) at lowest nonzero position (e.g. 110100 \( \rightarrow \) 111000)

(G4) If \( error(f, \text{subsets}) > \text{Bound} \)

\{ Precision := Precision + 1; Goto (G2) \}

Figure 1: Greedy algorithm to generate \( N \) input sets, subsets from \( X \), according to function \( f(X) \).

Below are the subsets which have been found by the heuristic algorithm of Figure 1 according to Table 1. All of them assume a parameter with 32 bit precision \( X = [b_0 b_1 \ldots b_{31}] \), and have been generated to guarantee an error less than \( 2^{-28} \). In the notation below we denote bits included in the subset by 1 and missing bits by 0.
